ACKNOWLEDGEMENTS

This report was funded in part by the Alabama Department of Economic and Community Affairs, Office of the Governor of the State of Alabama; and in part by a grant from the Office of Ocean and Coastal Resources Management, National Oceanic and Atmospheric Administration, United States Department of Commerce. The author wishes to express his kindest appreciation to Carolyn Merryman, David Wigger and Clinton Townsend of the ADEM Mobile Branch Laboratory for their diligence and many long hours spent processing and analyzing the samples. Thanks also to Mark Register, Nancy Van Antwerp, Michael Boyle, Al Hickey and Kelly Williams for their invaluable assistance collecting the samples. Regards also are extended to Dr. Steven Schropp, Dr. Herbert Windom and Dr. Wayne Isphording for their advice and technical assistance in preparing this paper.

EXECUTIVE SUMMARY

This report details the application of the concept of utilizing aluminum as a "normalizing factor" for interpreting metals data in coastal sediments. Accurate interpretation of such information is often complicated by the various factors influencing metals concentration in sediments. These factors may be natural, like the geology of the drainage basin and sediment grain size to name a couple, or they may be anthropogenic such as wastewater discharges from industrial processes, development of offshore hydrocarbon resources and shipyard activity. Utilization of aluminum as a so-called "geochemical normalizer" allows for an accounting of the natural variability of metals in sediments and for the identification of sediments enriched with metals relative to expected natural concentrations.

The principle of utilizing aluminum as a "normalizing factor" is based on the constant relationships existing between metals and aluminum in the earth's crust and in natural sediments. This concept has been successfully employed by investigators in other states for developing a method for identifying anthropogenic enrichment of coastal sediments.

Samples of sediments from coastal Alabama were collected and analyzed for their metals content. Metal/aluminum regressions, correlations and prediction limits were calculated and graphical plots of these relationships were constructed. The results indicate statistically significant relationships between aluminum and eight other metals. Metals data from coastal sediments can now be plotted on

these diagrams of the relationships assessed to determine if the metals content of the sample is within natural ranges or represents an enriched area.

The efforts of this study accomplished several objectives, these being: 1) verifying the validity of applying the concept of aluminum as a "normalizing factor" for the sediments of coastal Alabama, 2) defining metal/aluminum relationships for "clean" sediments in coastal Alabama, 3) tentative identification of areas of potentially enriched sediments, and 4) incorporation of a thorough and comprehensive Q&A program evaluating performance of the laboratory through use of reference standards and participation in an intercalibration exercise.

INTRODUCTION

The estuaries of coastal Alabama have become subjects of increasing concern relative to environmental stresses from developmental activities. These stresses may be in the form of industrial and municipal wastewater discharges, urban non-point sources, agricultural runoff, dredging and port and marina development. Of particular interest is the potential of these activities for enriching aquatic environments with heavy metals.

The sources of heavy metal enrichment are numerous and varied. These sources range in size from metal plating shops discharging small quantities on an intermittent basis to large facilities discharging millions of gallons daily of treated wastewater containing various heavy metals. Lead from the exhaust emissions of engines burning leaded gasoline also ends up in aquatic environments as a result of atmospheric deposition and direct input from boat motors. Additional sources common to coastal areas include the marine paints and surface coatings utilized in the shipbuilding industry. These preparations, designed for protection against corrosion and inhibition of the growth of fouling organisms, are based on heavy metal formulations toxic to many species of estuarine life. The uncontrolled release of these materials from the removal of old paint by sandblasting and the spray application of new coatings has, over the years, been a long standing source of metal enrichment to aquatic environments. A more recent and controversial source of potential enrichment of metals in the environment has been the development of offshore hydrocarbon reserves. The exploration and

production activities characterizing offshore development are accompanied by the use of clay-based drilling fluids and the generation of considerable quantities of geological formation cuttings from the well hole. The resultant waste drilling fluids and cuttings are rich in metals not common to estuarine sediments. The uncertain potentials for adverse impacts to aquatic ecosystems from these numerous sources have prompted federal and state regulatory agencies to examine more closely the effects of metal enrichment on sediment quality.

Consequently, needs have arisen for the investigation of the metal content of sediments throughout the Alabama coastal area. Specific needs from a regulatory perspective are:

1. Determination of "background" levels of metals in sediments of the entire coastal area, or in other words the concentrations of metals attributable to natural causes.
2. Development of a "standardized" method for sampling and analyzing sediments and interpreting the data for meaningful results.
3. Application of a "standardized" method along with a database of natural levels of metals in sediments in order to ascertain the degree of metal enrichment resulting from anthropogenic sources.
4. Identification of potential "hot spots" or areas of highly enriched sediments which may constitute a hazard to aquatic life and may require remediation.

Previous studies of sediment chemistry in coastal Alabama, Malatino

(1980) and Isphording (1985 and 1987), dealt with Mobile Bay and Mississippi Sound but did not examine the smaller estuaries or tributary streams. Although these previous studies generated a useful database for future reference of metals in sediments the investigators did not delve into developing a standardized method for identifying polluted sediments.

Schropp and Windom (1988) and Windom et al (1989) examined metal concentrations in estuarine sediments from coastal Florida and Georgia and developed a method for identifying metal enrichment due to anthropogenic activities. This method is based on the naturally occurring relationships between aluminum and other metallic elements. These relationships allow for the identification of polluted sediments by using aluminum as a reference element. The basis for this method is that aluminum occurs naturally in all estuarine sediments and the concentrations of other metals tend to vary with the concentration of aluminum. These naturally occurring proportions of metals relative to aluminum have been reported by several investigators (Turekian and Wedepohl, 1961; Taylor, 1964; Duce et al, 1976) to be fairly constant. This allows for the use of aluminum as a reference element or "normalizing factor" for identifying sediments enriched by anthropogenic activities. This concept has been used to examine metal pollution in the Savannah River estuary (Goldberg, 1979) and lead pollution in the Mississippi River (Trefey et al, 1985).

Although the principle of using aluminum as a "geochemical normalizer" was successfully employed in the above mentioned studies

it cannot be assumed that this applies to coastal Alabama. The geology of the drainage basins of the study area is characterized by clays exceptionally rich in aluminum (Isphording, pers. comm.) which could skew the statistical distribution of aluminum data. A non-normal distribution of such data complicates interpretation of results making reliable determinations of contaminated areas a difficult task (Sokal and Rohlf, 1969; Schropp and Windom, 1988). Other metallic elements, barium for example, are also naturally abundant in the clays of the area (Isphording, pers. comm.), these too might compound the difficulty of identifying anthropogenically enriched sediments. An additional complicating factor for Mobile Bay is the history of releases of aluminum enriched clays and stormwater runoff from the tailings ponds of an aluminum extraction facility previously operated in Mobile by The Aluminum Company of America. Although this facility has not operated in nearly a decade, stormwater runoff and the loss of spent bauxite ore from breaches in the walls of the tailings ponds have contributed some enrichment, albeit of an unknown magnitude and significance, to the lower Mobile River and Mobile Bay.

This study applied the concept of utilizing aluminum as a normalizing factor to metal concentrations in sediments of coastal Alabama. The goal of this effort being a standardized method for sampling, analyzing and objectively interpreting metals data for sediments. In achieving that goal a valuable database was compiled and preliminary identification of enriched areas was accomplished.

The results indicated that aluminum does account for most of the

variability of other metals except mercury. The scarcity of natural sources of mercury in the drainage basins of the study area would appear to account for this lack of covariance (Isphording, pers. comm.; Schropp, pers. comm.).

MATERIALS AND METHODS

Sediment samples (cores) were collected from 53 stations in coastal Alabama (Figure 1), the latitude and longitude coordinates of these stations are given in Table 1. The sites sampled encompassed a wide variety of sediment types ranging from aluminum and iron rich clays of the Mobile River Delta and upper Mobile Bay to the coarse grained silica rich sands of lower Perdido Bay. A K-B type core sampler (Wildlife Supply Co., cat. no. 2402-A12) equipped with a cellulose-acetate-butyrate liner tube was used for retrieval of sediment samples from sites where the water depth was greater than one meter; where the water depth was less than one meter samples were collected by utilizing the liner tubes as hand core samplers. The upper five centimeters of each core was placed in a clean glass jar and capped with a teflon lined lid. Samples were collected in triplicate, two samples for immediate processing and the third sample was "archived" in a freezer for future analyses in case of widely varying results between the first two.

Preparation of sediments for analyses began with oven drying samples at 60°C followed by weighing out a 0.25 gram portion of each. Each weighed portion was then placed in a 30 mL teflon cup to which was added nitric acid, hydrofluoric acid and perchloric acid. The teflon cups were then heated on a hotplate at ca. 120°C, each cup remaining on the hotplate until the sample had been totally digested, acid was added to each cup as needed until digestion was completed. Once the sample was digested, heating was continued until the sample volume was reduced to approximately 1 mL to which 2.5% nitric acid was added to bring the

sample volume up to 25 mL. Samples were then analyzed with a Perkin-Elmer 3030-B atomic absorption spectrophotometer (AA) using a flame furnace for Al, Fe and Zn and a graphite furnace for As, Ba, Cd, Cr, Cu and Pb. A Perkin-Elmer 460 AA equipped with cold vapor apparatus was used for analyses of samples for Hg.

The mean values of the analyses of replicate samples were utilized as data for statistical comparisons. Statistical procedures employed in this study are detailed in Sokal and Rohlf (1969) and Filliben (1975).

Quality of analytical technique was assured through participation in the intercomparison exercise for sediment metal analyses (FDER, 1991). This exercise involved the digestion and analyses of standard reference sediments from the National Institute of Standards and Technology (NIST SRM 1646) and the National Research Council of Canada (NRC BCSS-1 and BEST-1). Coastal sediments of a variety of types were also incorporated in the intercomparison exercise. Analytical results obtained by the ADEM Mobile Branch Laboratory were compared to those of other labs participating in the exercise. These results indicate a high degree of reliability in the analytical data produced by the ADEM lab. In addition to participation in the intercalibration exercise, ADEM laboratory personnel routinely checked performance of their digestion technique and analytical instruments by testing samples of reference material during the course of this study.

RESULTS

Application of the concept of utilizing aluminum as a reference element in conjunction with parametric statistical analyses demands that the data for metals have constant variance and a normal distribution. The test for constant variance was performed by constructing plots of sample means versus sample standard deviations for each metal. Standard deviations were proportional to mean values for all metals. Mean values for metals were then converted to log-10 values and plotted against standard deviations. The proportionality between mean values and standard deviations was removed indicating the presence of constant variance in the data set.

Presence of normal distribution was determined by calculating normal scores for a sample size of $N=53$ and plotting them against the data for sediment metals concentration. The presence of a relatively linear plot indicating a normal distribution. This procedure was performed for both absolute concentrations and for log-10 transformed values. Some elements, aluminum, chromium and iron, appeared to fit a normal distribution using absolute concentrations whereas others, arsenic and cadmium, required a log-10 transformation to conform to a normal distribution. The remaining elements, barium, copper, lead, mercury and zinc, failed this graphical test for normal distributions regardless of using untransformed or transformed data. Graphical representation of these results are shown in Appendix A. Presence of normal distributions was tested in a more rigorous manner using the probability plot coefficient test (Filliben, 1975). Obtaining a significantly high correlation coefficient between normal scores and

metals data leads to the acceptance of the null hypothesis (H_0) of normality and the rejection of the alternative hypothesis (H_a) of non-normality, results of this test are shown in Table 2. Untransformed arsenic, barium, cadmium, copper, mercury, lead and zinc deviated from normality. Untransformed aluminum, chromium and iron values fit a normal distribution. Log-10 transformed arsenic, cadmium and zinc data produced normal distributions but transformed data for barium, copper and lead yielded coefficients just short of the critical value. Both untransformed and log-10 transformed data for mercury failed to conform to a normal distribution.

The untransformed values for aluminum were utilized as the independent variable for all comparisons in this study. Untransformed values for chromium and iron served as dependent variables for those elements; log-10 transformed data were utilized as the dependent variable sets for arsenic and cadmium. As mentioned above the data for barium, copper, lead and zinc did not exhibit a normal distribution; however, when samples that were suspected of being enriched were removed from the data set these elements also exhibited a normal distribution. Once again, mercury failed to conform to a normal distribution even as a "trimmed" set of data. A discussion of "trimming" the data set and analyses of data from "clean" sites follows later in this section.

Having examined the data for normality and constant variance the next step was to determine the strength of metal/aluminum relationships. Correlation coefficients were calculated for each metal and aluminum, these are listed in Table 3. Concentrations of all metals except

mercury were positively correlated with aluminum concentrations ($p < 0.005$). Iron and chromium displayed the strongest relationships with aluminum; cadmium the weakest. Mercury showed a weak inverse correlation with aluminum and consequently was not referenced to aluminum values. Schropp and Windom (1988) found a similar inverse relationship between mercury and aluminum and also refrained from comparing mercury values to aluminum values.

The next step was to analyze the data for associations between the independent variable, aluminum, and dependent variables, other metals. Least squares regression analysis was used to evaluate the relationship between the metal concentrations and aluminum concentrations. Results of the regression analyses are presented in Table 4.

The results of the regression analyses were then utilized to calculate 95% prediction limits according to the procedure of Sokal and Rohlf (1969). Regression lines and prediction limits for each metal are plotted in Appendix B, superimposed on the metal vs aluminum graphs.

The analytical result of each metal was then plotted against its respective aluminum value. These are graphically represented in Appendix B. Superimposed on the graphs are the regression lines and 95% prediction bands for each metal/aluminum relationship. These results indicate a proportional relationship between the concentration of aluminum and the other metals except for mercury. Data for all metals is presented in tabular form in Table 5.

Table 2

Probability plot correlation coefficients
for normality of metals data.

So far this exercise has demonstrated statistically significant relationships between aluminum and the metals arsenic, cadmium, chromium, iron and zinc. The metals barium, copper and lead did not fit a normal distribution but appeared to be somewhat skewed to the left indicating a data set enriched in these elements. Since the primary objective of selecting sample sites was the sampling of a broad spectrum of sediment types rather than selecting only those sites far removed from sources of potential contamination, there was the chance that some samples were enriched due to anthropogenic activity. The next part of the discussion deals with examination of a "clean" set of data.

As stated above, the intent of choosing the locations was directed more towards thorough coverage of the coastal area and a wide variety of sediment types rather than avoiding potentially contaminated areas. The observed lack of normality in the data for barium, copper and lead, combined with the potential for enrichment of the sediments of western Mobile Bay from urban non-point sources, the extensive industrial activity in the Mobile area and from the sources discussed in the introduction led to deleting from the data set those samples from the western half of Mobile Bay including the tributaries. Additional rationale for this action was provided by analyses of sample material from a ditch draining a bauxite tailings impoundment at the old ALCOA facility. This material was a fine grained "mud" typical of the contents of the impoundment. These results indicate that the material collected from the ditch was indeed enriched with aluminum far above that of any sample of natural sediment collected during this study. The nature and quantity of bauxite mud in the ditch together with the

direction of drainage (towards the Mobile River) appears to indicate that the tailings impoundments have been a likely source of metals enrichment to Mobile Bay.

Subsequent analyses were performed on this set of data, sample size $N=38$, referred to hereinafter as the "clean" data set.

Statistical analysis of the "clean" data set was handled the same as for the entire data set. Graphical plots of normal scores versus concentration values were constructed and the probability plot coefficient test was applied. The results of these procedures indicate a normal distribution for the untransformed values of barium, chromium, copper, iron, lead and zinc, and for the log-10 transformed values of arsenic and cadmium. Graphical representation of these plots may be found in Appendix C and probability plot correlation coefficients in Table 6. The presence of homoscedasticity was tested by the same method as discussed earlier.

After determining that the "clean" set of data meets the requirements of parametric statistical analyses, the "clean" set was subjected to least squares regression analyses (Sokal and Rohlf, 1969). The results of which are presented in Table 7, correlation coefficients, and Table 8, regression equations. The correlation coefficients for the "clean" data set show a relationship between aluminum and metals approximately the same as those for the entire data set. Although "trimming" the data may not have strengthened the metal/aluminum relationships of the "clean" data set, it did result in normal

distributions for barium, copper and lead, indicating possible enrichment for these elements in sediments of western Mobile Bay.

The results of regression analyses were then utilized to calculate 95% prediction limits as with the entire data set. The graphical plots of metals vs aluminum complete with regression lines and 95% prediction limits for the clean data set are presented in Appendix D. As the reader will observe the width of the prediction limits vary among the different elements. This is a function of the correlation coefficients for the metal to aluminum relationships, as the magnitude of the correlation coefficients increase the width of the prediction limits decrease.

Table 6

Probability plot correlation coefficients
for normality of clean sites metals data.

| Metal | Correlation Coefficient | |
|----------|-------------------------|--------------------|
| | Untransformed | LOG 10-Transformed |
| Aluminum | 0.955 * | 0.919 # |
| Arsenic | 0.868 # | 0.978 * |
| Barium | 0.963 * | 0.903 # |
| Cadmium | 0.837 # | 0.978 * |
| Chromium | 0.971 * | 0.943 # |
| Copper | 0.977 * | 0.948 # |
| Iron | 0.957 * | 0.913 # |
| Mercury | 0.861 # | 0.853 # |
| Lead | 0.968 * | 0.949 # |
| Zinc | 0.967 * | 0.959 # |

| Zinc | 1.049655 | 0.000015 |

a = Y-intercept of regression line.
b = Slope of regression line.

DISCUSSION

Application of the results of this study to monitoring efforts is fairly straightforward. The regression line and prediction limits of a specific metal to aluminum relationship from the "clean" set of data are reproduced on a graph either by hand or by means of computer graphics software. Then the value of a metal at a station is determined (utilization of mean values calculated from replicate or triplicate samples from each station is strongly recommended) and points representing the corresponding metal to aluminum values are plotted on the graph. If a point falls within the prediction limits then the metal is within the natural limits. If a point lies above the upper prediction limit then the sample is considered enriched in that specific metal. The greater the distance above the upper prediction limit, the greater the chance that the sample is from an enriched area and the greater the degree of enrichment of that sample.

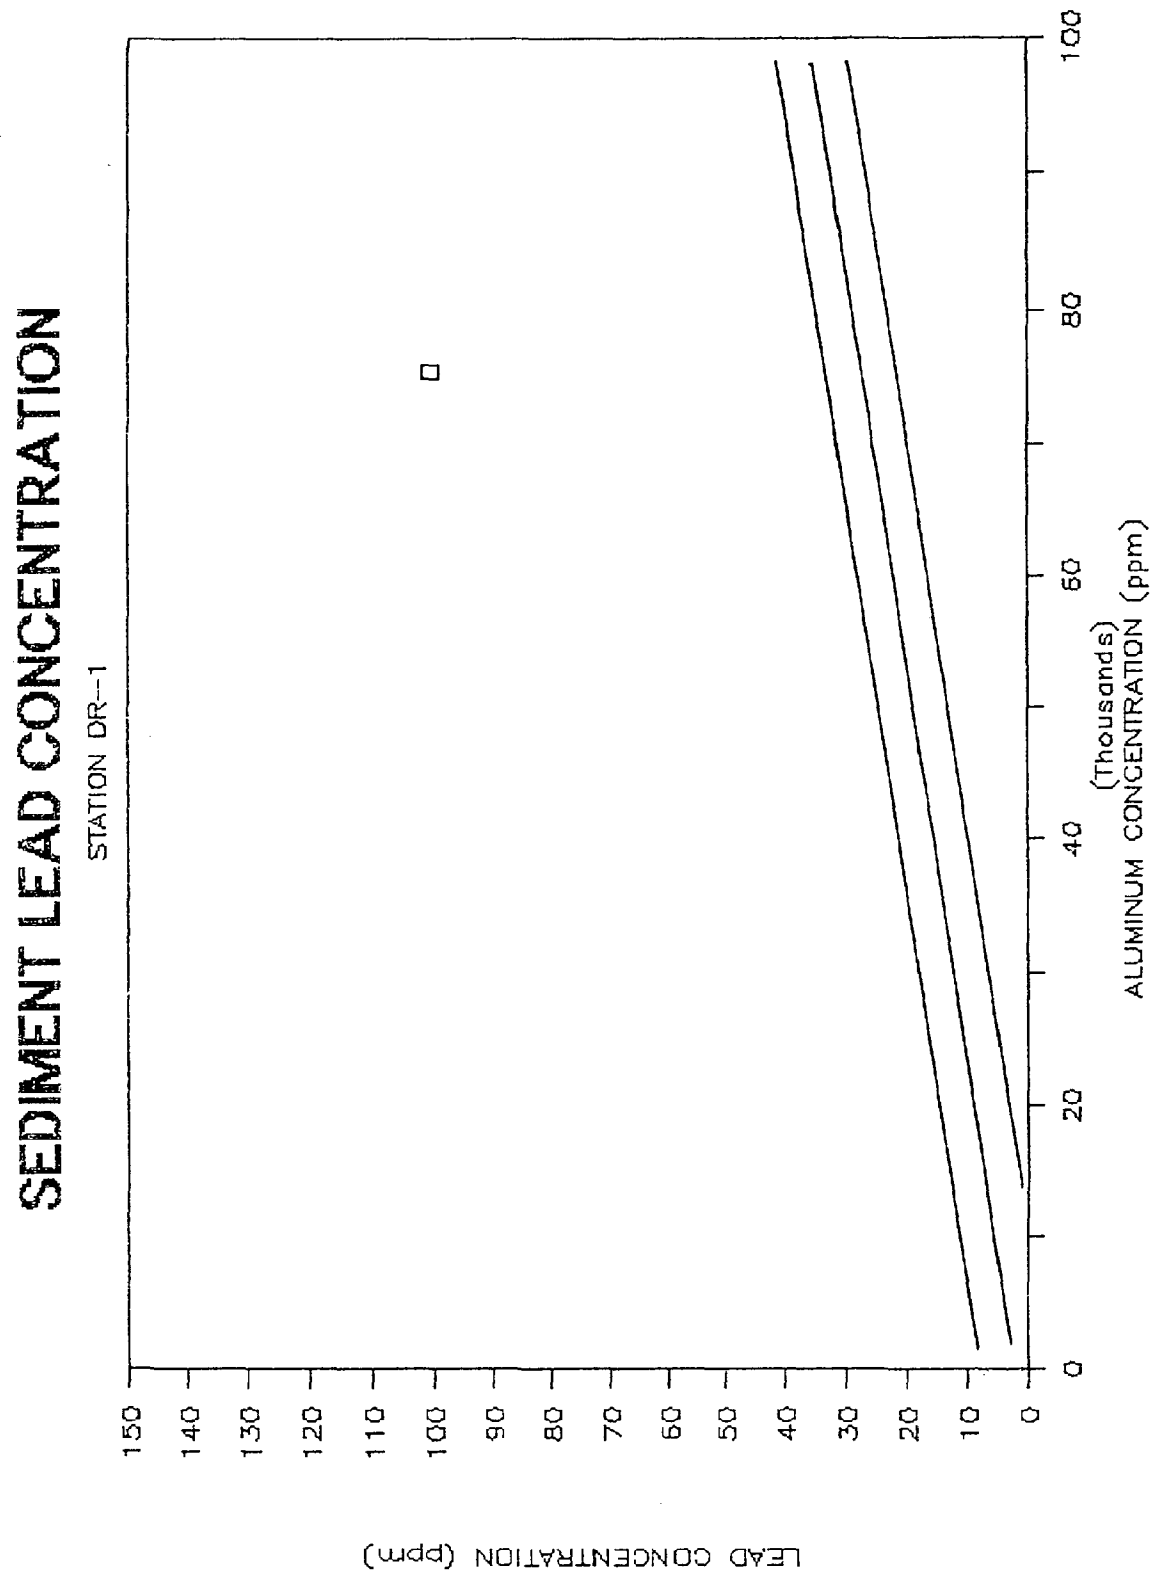

An example of this procedure is as follows. During our sampling we collected sediments from Dog River a tributary of Mobile Bay, this site is referenced to as station DR-1 in the data table and on the map. This stream is located in an extensively developed watershed and receives a considerable amount of stormwater runoff from paved roads, parking lots and other urban non-point sources. The site where sample DR-1 was collected is also a popular recreational area with a high density of boat traffic. Consequently this location has been subjected to years of exposure from emissions from boat motors and motor vehicles. Consultation of the data in Table 2 reveals this site to also be the one with the highest lead concentration of all sites sampled.

With this in mind site DR-1 was deleted from the clean data set and was chosen as a test case for evaluation of possible enrichment with lead. The value for lead at this location was then plotted on a graph of the lead/aluminum relationship. This example is illustrated in Figure 2 and shows the lead concentration to be well above the upper prediction limit. From this, it is reasonably certain to conclude that the sediments at this site are enriched with lead. This information along with knowledge of the geology and land use practices of the drainage basin would appear to indicate that exhaust emissions from internal combustion engines are the likely source of enrichment. Of course this preliminary assessment should be followed up with a more extensive survey of sediments in the river basin.

Although this method appears to be a useful tool for identifying areas of enriched sediments the author offers the following caveat so as to minimize the chance of misinterpretation of data. Points lying on or just above the upper prediction limit should be evaluated with caution. Such judgements are best made when assisted by analyses of samples from nearby stations and ancillary data such as proximity and nature of wastewater discharges and/or non-point sources. Also, the necessity for utilizing the mean value of the analyses of duplicate or triplicate samples cannot be emphasized too strongly. Widely varying results for replicate samples from a station may be an indication of errors in the digestion and analytical procedures. Additionally, an effective laboratory Q&A program is invaluable for obtaining reliable results and if possible should incorporate certified reference sediments such as those available from the National Institute of Standards and Technology.

Sediment lead at Station DR-1

CONCLUSION

The results of this study appear to have established the existence of statistically significant relationships between aluminum and eight of the nine metals analyzed in "clean" sediments from Alabama estuaries. The relationships are defined by the regression lines for each metal vs aluminum, estimates of the ranges of values to be expected from samples of clean sediments in Alabama are given by the prediction limits. The regression lines and prediction limits of the "clean" data set can be used to identify unnatural concentrations of metals in sediments from Alabama estuaries.

This technique will be applied in the near future to a survey of shipyards in coastal Alabama. The objective of this study will be the evaluation of metals enrichment of sediments in and around shipbuilding facilities. These results are to be reported in a forthcoming document.
